# A robust and cooperative parallel tabu search algorithm for the maximum vertex weight clique problem 

#### Abstract

The maximum vertex weight clique problem (MVWCP) is a challenging NP-Hard combinatorial optimization problem that searches for a clique with maximum total sum of vertices' weights. In this study, we propose a robust and cooperative parallel tabu search algorithm (PTC) for the MVWCP. Our proposed algorithm uses a dedicated tabu search algorithm with a multistart strategy for the diversification of search space on a parallel computation environment. An effective seeding mechanism is developed with respect to the rank of the processors to choose diversified starting points for better exploration areas. Classical add, swap and drop operators of tabu search are improved for parallel computation with a combined neighborhood approach. The PTC algorithm is evaluated on a set of 120 problem instances from DIMACS-W and BHOSLIB-W benchmarks. Computational results show that the PTC algorithm competes with state-of-the-art heuristic algorithms by reporting average best (optimal) result hit ratios up to $99.0 \%$.

Keywords: Maximum clique; tabu search; parallel computation; cooperation; heuristics.

## 1. Introduction

The maximum clique problem (MCP) is to find a complete sub-graph with a maximum cardinality in a given general graph [1]. The MCP can be used to design and solve several problems in computer vision, pattern matching, image matching, economics, examination planning, financial networks, social network analysis, wireless network telecommunications, bioinformatics and chemoinformatics [2]|3]. In addition to this, clique partitioning, max-min diversity, graph vertex coloring, sum coloring and optimal winner determination are some of the other important combinatorial optimization problems that are related with the MCP [4, 5]. The maximum vertex weight clique problem (MVWCP) is a generalization of the classical MCP. When the vertices of the graph are assigned value 1 , MVWCP is equivalent to MCP that finds a maximum cardinality clique [6][7]. The decision version of MCP is NP-complete and the generalized MVWCP is at least as hard as MCP [8][9]. More formaly, given an undirected graph $G=(V, E)$ with vertex set $V=\{1, \ldots, n\}$ and edge set $E \subseteq V \times V$. Let $w: V \rightarrow Z^{+}$be a weighting function that assigns to each vertex $i \in V$ a positive integer. The MVWCP determines a clique of maximum weight.

Tabu Search is an efficient meta-heuristic with a local heuristic search procedure to explore a solution space and it has been successfully applied to the solution of several combinatorial optimization problems [10]. In this study, we enhance the capacity of a classical tabu search algorithm [7] with parallel computation and adapt classical operators add, swap, and drop operators to the parallel computation environment. Restarting mechanism of the proposed algorithm (PTC) has a significant improvement on the average success hit ratio of the algorithm. The PTC algorithm is aware of stagnation and restarts the optimization process from different initial cliques when it gets stuck into local optima. This procedure is coordinated in the parallel computation environment and slave nodes use their exploration areas during the optimization. Our proposed PTC algorithm shows a more robust behaviour than other heuristic algorithms. The parallel version of tabu search enhances the robustness property of the algorithm by obtaining up to $99 \%$ of the reported best (optimal) result hit ratios in the literature.

In Section 2, related studies for the state-of-the-art MVWCP are summarized. In Section 3, our proposed algorithm, PTC, is introduced. Section 4 gives the details for the performance evaluation of the experimental results and comparison of the PTC algorithm to the state-of-the-art algorithms on benchmark instances DIMAC-W and BHOSLIB-W. Concluding remarks and future work are provided in the last Section.

## 2. Related work

In this section, we give information about the state-of-the-art algorithms proposed for the solution of the MVWCP [6]. Several algorithms have been proposed for solving MVWCP for the last 20 years. These algorithms can be examined in two parts, exact and heuristic algorithms. Östergärd propose a branch-and-bound ( $B \& B$ ) algorithm in which the vertices are processed according to the order provided by a vertex coloring of the given graph [11]. Kumlander develop a backtrack tree search algorithm which relies on a heuristic coloring-based vertex order [12]. Warren \& Hicks propose three $B \& B$ algorithms that use weighted clique covers to generate upper bounds and branching rules [13]. Wu \& Hao develop an algorithm that uses new bounding and branching techniques with specific vertex coloring and sorting [4].

Heuristic methods are recent popular algorithms to obtain (near-)optimal solutions in practical computing times when the search space of the problem space is too large to be calculated by an exact algorithm. Some of the most important heuristic algorithms are listed below. Mannino \& Stefanutti propose a tabu search algorithm based on edge projection and augmenting sequence [14]. Fang et al. present an algorithm that uses Maximum Satisfiability Reasoning as a bounding technique [15]. Bomze et al. design MVWCP as a continuous problem that is solved by a parallel algorithm using a distributed computational network model [23]. Busygin proposes a trust region algorithm [25]. Singh \& Gupta introduce a hybrid method combining a genetic algorithm [17]. A partially enumerative algorithm is presented for the maximum clique problem which is very simple to implement by Carraghan \& Pardalos [16]. Pullan \& Hoos develop the Phase Local Search (PLS) algorithm for the classical MCP to MVWCP [18]. Wu et al. develop a tabu search algorithm by integrating multiple neighborhoods [7]. Benlic \& Hao present the Breakout Local Search algorithm that explores multiple neighborhoods and applies both directed and random perturbations [19]. The general binary quadratic programming (BQP) model has been widely applied to solve a number of combinatorial optimization problems. Wang et al. recast the MVWCP into a model which is solved by a probabilistic tabu search algorithm designed for the BQP [20].

Grosso et al. formulate and analyze iterated local search algorithms for the MCP. The basic components of such algorithms are fast neighbourhood search, diversification techniques and restart rules [21]. Zhou et al. introduce a generalized move operator called PUSH that generalizes the conventional ADD and SWAP operators commonly used in the literature and can be integrated in a local search algorithm for MVWCP [22]. Nogueira et al. present a hybrid iterated local search (ILS) algorithm for the maximum weight independent set (MWIS) problem. MWIS is a problem that is closely related to MVWCP. In their study, two new neighborhood structures are introduced and they are explored using the variable neighborhood descent procedure. The results show that the hybrid ILS is capable of finding all known optimal solutions [24]. Malladi et al. introduce the Clustered Maximum Weight Clique Problem (CCP), a generalization of the MVWCP, that models an image acquisition scheduling problem for a satellite constellation [34]. Wider information about the algorithms to solve MVWCP can be found in a literature survey by Wu \& Hao [6]. El Baz et al. propose a parallel ant colony optimization based metaheuristic (PACOM) for solving MVWCP [28]. This is the only parallel heuristic algorithm that we have found out in literature for MVWCP. Its results are given for DIMACS-W problem instances. To the best of our knowledge, there is no parallel tabu search algorithm like ours designed for the solution of MVWCP.

Contemporary software/hardware support can provide instruction level parallelism and gain performance increases. However, they do not perform as well as the human designed parallel algorithms. Our proposed algorithm, PTC, intends to explore different areas of search space concurrently rather than only speeding-up the search velocity of a single tabu-search process. There are recent and successful approaches of parallel heuristic algorithms to solve combinatorial optimization problems such as quadratic assignment and bin packing problems [26, 27, 29]. Our approach is one of its first examples that is applied to the solution of the MVWCP.

## 3. Proposed algorithm, Parallel-Tabu-Clique (PTC)

In this section, we present our proposed Parallel-Tabu for Clique (PTC) algorithm for the MVWCP. PTC is a parallel tabu search algorithm implemented by using $\mathrm{C}++$ programming language and Message Passing Interface (MPI) libraries. The PTC introduces a novel diversification mechanism to improve the efficiency of the algorithm by making use of alternative seeding support for the starting points and randomization of the search process. This mechanism is designed with respect to the rank number of the processors. A distributed probabilistic restarting process is employed with the proposed PTC algorithm. Classical add, swap, and drop operators of tabu search that are used for constructing a maximum clique are adapted to the distributed computation environment. A master and slave communication topology is used during the communication of processors.

### 3.1. Motivation for parallel heuristic optimization algorithms

Tabu search is really an efficient heuristic that has been used for the optimization of several NP-Hard combinatorial optimization problems [7][10]. However, as most of the heuristics, tabu search tries to find the optimal value by calculating the fitness value of each neighbor solution. This is a process event that consumes a serious amount of time. Classical single-processor heuristic algorithms have this disadvantage of calculating the fitness values more slowly than parallel heuristic algorithms [30|[32][33]. Techniques such as dynamic programming can reduce this cost significantly but it is not always possible to apply these techniques. In our opinion, a scalable parallel algorithm that quickly calculates the fitness of the new solutions is a very important means of computation for better optimization. There is a classical way of understanding the parallel algorithms as tools of speeding-up the computation. However, with the heuristic methods it provides more than just being a faster way of execution. With the parallel heuristic algorithm we propose, we intend to increase the possibility of obtaining the optimal results through faster computation and diversified search methods of parallel implementation. All the processors seed themselves from different initial points, which is a very effective way of exploring the search space.

### 3.2. Fitness value of a possible MVWCP solution

In this section we give information about the fitness value of a solution. The MVWCP is a maximization problem in a given graph $G=(V, E, w)$ where $V$ is the set of vertices, $E$ is the set of edges and $w$ is a weight function that assigns a positive number to each vertex. The PTC algorithm searches space $\Omega$ (set of all the cliques in $G$ ) for a maximum total sum. For a solution (clique) $C \in \Omega$, its fitness value can be given as a function of $W(C)=\sum_{i \in C} w_{i}$ where $W: \Omega \rightarrow Z^{+}$. The neighbors of $C$ are possible elements of $V$ that are not in the set of $C$ and when a new clique $C^{\prime}$ is constructed by adding a new vertex and $W\left(C^{\prime}\right)>W(C)$ then a better solution is obtained during the optimization process of the PTC algorithm.

### 3.3. Initialization of a candidate maximum vertex weight clique solution

For each processor in a parallel computation environment, the PTC algorithm begins with a different starting clique, $C$. This is provided by a mechanism that generates random numbers with respect to the rank of the processor in the parallel computation environment. Therefore, the larger amount of processors you have, the more likely the PTC algorithm will explore the search space better. The PTC algorithm uses a parallel version of the tabu-search to improve the weight of clique $C$. In order to construct an initial $C$, the PTC algorithm selects a vertex $i$ from $G$ and initializes the clique $C$ to the set consisting of this single vertex that is selected as a different starting point for each processor in the environment. Later, another vertex $v \notin C$ that has a connection with every vertex in $C$ is selected continuously. This iteration goes on until no such vertex $v$ exists. This is a simple and fast process with diversified initial solutions for each iteration of the tabu search procedure at each different slave. When two possible vertices are considered then one of them is selected randomly with respect to the seeding mechanism of the processor.

### 3.4. Operators of the PTC algorithm

The PTC algorithm explores the optimal value by using three basic operators (add, swap and drop) jointly.
Add operator increases the total sum of the weights by introducing a new vertex to the clique. Therefore, add operator has always a positive effect on the existing solution. But it is not always possible to add a new vertex to the existing clique and it is a costly operation to verify this. The complexity of $a d d$ operation is $\mathrm{O}(n)$ where $n$ is the number of vertices.

Swap operator exchanges one of the vertices in a clique with another one that is outside of the solution. This operation may lead to a better result or not. It depends on the values of the vertices that are swapped. But this exchange of the vertices may lead to a better maximum vertex weight clique. Sometimes, it is possible to have better results than applying add operator. In Figure 1, we can see how a swap operator produces a better solution than an add operator (see the total cost of each clique after add and swap operations. Original clique has a total cost of 15 after add operation whereas the total cost is 21 with swapping.).

Drop operator removes a vertex from the existing solution. It always decreases the total cost of the maximum vertex weight clique. However, it does not mean that it will not help us explore better solutions. Instead, it has a positive effect for the diversification of the search.

It is not wise to say that $a d d$ operator has always a better influence for the optimization of the problem. There may be situations that an add operation cannot be executed. In such cases, swap and drop operators can easily diversify our search space and rescue us from local optima. Therefore, we cannot talk about supremacy of a specific operator. The best operator depends on the landscape of the search area and initial cliques. Moreover, using these operators in a union fashion is reported to be an efficient way of optimization of the MVWCP [7].

Parameter $L$ (search depth) limits the search process for consecutive iterations without improving the clique weight. It means when there is no improvement in the result, the tabu search does not further keep on spending its exploration on this constructed solution instead it restarts a new solution.

Figure 1. The swap operator exchanges the vertices 1 and 2 from clique $C=\{1,5,6\}$ to produce a new maximum vertex weight clique $C^{\prime}=\{2,5,6\}$. add operator that introduces vertex 3 to the existing clique does not produce a better maximum vertex weight clique.

The PTC algorithm uses a distributed tabu list to restrict the revisiting of previously searched solutions. At every processor's memory there is a tabu list that works independently for each tabu search process. When a vertex leaves the current clique by using a swap or drop operator it is forbidden to include this vertex into the same solution clique for the defined iteration times. This iteration is called tabu tenure. A vertex can leave the clique by using drop or swap operator without any constraint. A move is called as tabu if one of its attributes is tabu and use the aspiration criterion that lets a move to be executed even if it is a tabu and it generates a solution better than any existing solution. A move that satisfies the aspiration criterion and not tabu is permitted to be executed in tabu search.

PTC algorithm explores three neighborhoods at each iteration and moves toward a move that produces the best solution. The three neighborhoods enhances the algorithm to make a better exploration of the candidate solutions. Tabu list provides an area that should not be visited again and provides a good diversification mechanism. This is performed concurrently by several processors during the optimization. Multistart is another diversification process that is employed by the PTC algorithm. The details of the tabu search and parallel execution of the processors can be seen in Algorithms 1 and 2 respectively. Master processor is receiving the results from slave processors while it is also making a tabu search and improving the quality of the solution. In Figure 2, the flowchart of the PTC algorithm is presented.

Figure 2. Flowchart of the PTC algorithm.

### 3.5. Communication topology of the PTC algorithm

The PTC algorithm uses a master and slave communication topology during the execution of the algorithm. All the processors in the environment (including the master) start their tabu search process. After executing tabu search optimization 100 times, they send their solutions to the master node. Master node receives all the results coming from the slaves and report the best solutions and the other statistics obtained during the optimization process.

```
Algorithm 1: The multi-neighborhood tabu search algorithm for MWCP [7]
    Input: A weighted graph \(G=(V, E, w)\), integer \(L\) (search depth), Iter \(_{\text {max }}\) (max. number of iterations)
    Ensure: \(C^{*}\) is a clique with weight \(W\left(C^{*}\right)\)
    Iter \(=\) null \(/ /\) counter for iterations
    \(C^{*}=\emptyset\)
    /* number times that tabu search is restarted from different vertices*/
    while \(\left(\right.\) Iter \(<\) Iter \(_{\text {max }}\) ) do
        C = Initialize()
        Initialize tabu_list
        \(\mathrm{N}=0 / /\) iterations that \(W\left(C^{*}\right)\) is not improved
        \(C_{\text {local_best }}=C / / C_{\text {local_best }}\) is the local best Clique found until now
        while \(N<L\) do
            Construct neighborhoods \(N_{1}, N_{2}\), and \(N_{3}\) from \(C\)
            Choose the best neighbor \(C^{\prime} \in N_{1} \cup N_{2} \cup N_{3}\)
            \(C=C^{\prime} / /\) current solution is new solution
            \(N=N+1\)
            Iter + +
            Update tabu_List
            if \(\left(W(C)>W\left(C_{\text {local_best }}\right)\right)\) then
                \(N=0\)
                \(C_{\text {local best }}=C\)
        if \(\left(W\left(C_{\text {local_best }}\right)>W\left(C^{*}\right)\right)\) then
            \(C^{*}=C_{\text {local }}\) best
    Return (Clique ( \(C^{*}\) ))
```

```

```

## 4. Performance Evaluation of the Experimental Results

In this section, we give information about our High Performance Cluster (HPC) experimental environment, problem instances of the MVWCP, performance evaluations (in terms solution quality and execution times), speed-up, and scalability issues of the proposed algorithm. We report the results of the proposed algorithm with the benchmark problem instances and compare its performance on those of other state-of-the-art algorithms.

### 4.1. Problem instances and experimental setup

We observe the efficiency of our PTC algorithm on DIMACS-W and BHOSLIB-W instances [31]. The DIMACSW benchmark has 80 instances from a variety of real life applications. The DIMACS-W benchmark has graphs generated randomly and maximum clique has been hidden by incorporating low-degree vertices. The problem instances range from 50 vertices and 1,000 edges to 3,300 vertices and $5,000,000$ edges. The BHOSLIB-W problem instances have been known to be difficult for maximum clique algorithms. Both DIMACS-W and BHOSLIB-W benchmarks have been widely used to test new MVWCP heuristics. The weighted DIMACS-W benchmarks are produced from the DIMACS benchmark instances by allocating weights to vertices. For each vertex $k, w_{k}$ is set equal to $(k \bmod 200)+1$ [35]. Each problem instance is solved 100 times by our proposed algorithm with different random seeds with respect to the rank of the processors. The maximum allowed iterations Iter ${ }_{\max }$ for each run and instance is set to $10^{8}$. For the search depth ( $L$ ), $L=4,000$ for the instances of the MWCP.

Our experiments are performed on a high performance cluster (HPC) computer. The machine has 46 nodes, each with 2 CPUs giving a total of 92 CPUs. Each CPU has 4 cores with a total of 368 cores. Each node has two 24 port Gigabit ethernet switches and one 24 port high performance switch. The software comprises; a Scientific Linux v4.5 64-bit operating system, Lustre v1.6.4.2 parallel file system, Torque v2.1.9 resource manager, Maui v3.2.6 job scheduler, Open MPI v1.2.4, and the C++. The instances are optimized by using 6 nodes, which means that 48 processors are used during the optimization process. For difficult instances, MANN_a27, MANN_a45, and MANN_a81, 128 processors are used to provide better results.

### 4.2. The effect of increasing the number of processors

We analyze the performance of the PTC algorithm with increasing number of processors. This experiment shows us whether additional processors will provide any advantage (better results) or not. Therefore, the results of this experiment are really crucial for scalability and effectiveness of our parallel heuristic algorithm. As we have explained earlier, main purpose of a parallel heuristic algorithm is not just to speed-up the calculation of the instructions but also explore the search space from possible different starting and diversified points of the problem. We select one of the hardest DIMACS-W problem instances (MANN_a27) as our test case instance. During our experiments we observe that this instance is really a difficult one and it would be interesting to observe the performance of our algorithm on this problem instance. Figures 3 and 4 show the number optimal solution hits and the average of the obtained results after 100 runs respectively. It can be easily observed that when the number of best result hits is 3 with a single processor, it becomes 74 with 128 processors. Similarly, a significant amount of increase is observed on the average number of the hits during the experiments.

Figure 3. The effect of increasing the number of processors on number of best results.
Figure 4. The effect of increasing the number of processors on the average of hits.
Tables 1 and 2 present detailed results of PTC algorithm on DIMACS-W and BHOSLIB-W benchmark problem instances respectively. Columns 1-3 define the properties of the problem instance. $\omega$ is the size of the largest known clique. Node is the number of vertices in the graph. At the other columns, we give some computational statistics about the optimization of the problem. The maximum weight obtained by PTC over the 100 runs ( $W$ _best ), the average weight over the 100 trials ( $W_{\text {avg }}$ ), the number of successful trials $W_{\text {best }}$ (Success), the average time (sec.) and the average iterations [7]. $W_{\text {best }}$ results are obtained from the study of Wu et al. [7] as most of the related studies do. When making comparisons with state-of-the-art algorithms we keep these standard values of Wu et al..

By looking at the results of the solutions, we can see that the cardinality of the obtained maximum weighted clique $|C|$ does not always have the same value with the maximum clique size $(\omega)$. Because maximum clique size $\omega$ does not mean that it will have the maximum weight of the whole graph $G$. There may be other smaller cliques with a larger total sum of vertices.

The hit ratio of the PTC algorithm is 100 (except for the instance MANN_a27) for all DIMACS-W instances. The PTC algorithm consumes a lot of time while solving the instances C2000.9, MANN_a27, MANN_a45, MANN_a81, and p_hat1500-3 in DIMACS-W benchmark. The average of the execution times is reasonable with the instances in this set. The execution times are observed to be higher for the BHLOBS-W benchmark instances in Table 2 That is because the number of nodes and edges are larger in this set of problems. The hit ratio of the PTC algorithm also decreases when the number of nodes and the edges are increasing in BHLOBS-W benchmark. For the problem instance frb30-15-1 with 450 nodes, the hit ratio is 100 but for the instance frb59-26-5 with 1,534 nodes, the hit ratio goes down to a ratio 6 .

The most important lesson we can get after these experiments is that the PTC algorithm provides a robust performance due to its parallel and diversified exploration capability. It can be concluded that when the algorithm is run 100 times with 48 processors (slave nodes), it can grantee the optimal solutions given in the stud of Wu et al..

Table 1. Detailed results of PTC algorithm on 80 DIMACS-W benchmark instances. node is the number of vertices, $\omega$ is the maximum clique size, W_best is the best value that is found until now, best-found is the best value found by the algorithm, avg-sum is the average of the results, hit is the number of obtained best results, $|C|$ is the cardinality of the obtained maximum weighted clique, avg-iter. is the average iteration performed during optimization.

Table 2. Detailed results of PTC algorithm on 40 BHLOBS-W benchmark instances.

### 4.3. Comparison with state-of-the-art algorithms

In this part of the experiments, we compare our results with those of state-of-the-art heuristic algorithms in literature. We compare our PTC algorithm with six recent heuristic algorithms designed for the solution of the MVWCP. The algorithms are the Phased Local Search (PLS) [35], Multi-Neighborhood Tabu Search (MN/TS) [7], Breakout Local Search (BLS) [19], ReTS-I [22], Iterated Local Search Variable Neighborhood Descent (ILS-VND) [24], parallel ant colony optimization based metaheuristic (PACOM) [28] and Binary Quadratic Programming (BQP) problem with the Probabilistic Tabu Search algorithm (BQP-PTS) [20]. All these algorithms are sequential and executed with a single processor. Because it is beyond our study to write parallel versions of all these algorithms and make a more fair comparison, we give the published experimental results of these algorithms.

For the other 118 instances, the PTC is able to provide better or the same results that have been found by the other algorithms. Algorithms ILS-VND, ReTS-I and BLS have the best observed results for the instances MANN_a45 and MANN_a81. These are the only two instances that PTC is not able to provide the best known results. When we take the average of the best results without including these instances, ILS-VND, ReTS-I, BLS and PTC have the same average values $(4,575.4)$. The PTC algorithm has the best average hit success of all the algorithms for the DIMAC-W ( $99.0 \%$ ) and BHOSLIB-W ( $85.1 \%$ ) instances. Tables 3 and 4 present the comparison of PTC algorithm with those of the state-of-the-art heuristic algorithms.

Table 3: Comparison with state-of-the-art algorithms on DIMACS-W problem instances
Table 4: Comparison with state-of-the-art algorithms on BHLOBS-W problem instances
Table 5 gives the execution times of state-of-the-art algorithms for selected problem instances from DIMACS-W and BHOSLIB-W benchmark. Its execution time is closer to sequential tabu search algorithm MN/TS. Generally all the state-of-the-art heuristic algorithms have practical optimization times for the instances. ReTS-I and ILS-VND algorithms have the best (shortest) execution times whereas BQP-PTS algorithm has the longest running time. The PTC algorithm has reasonable execution times on the average. The problem instances of our experiments range from 50 vertices and 1,000 edges to 3,300 vertices and 5,000,000 edges. Therefore, when an instance is small, the computation time of the optimization does not take much. However, due to the intractable complexity behavior of the problem, it
grows exponentially. This causes the fitness evaluation of the new solutions to consume a lot of computation power while using the operators, add, swap and drop.

Table 5: Execution times of state-of-the-art algorithms for some selected problem instances. Units are given as seconds.

A study by El Baz et al. that proposes a parallel ant colony optimization based metaheuristic (PACOM) for solving the MVWCP was the only parallel algorithm that we have come across during our literature survey [28]. The performance of the PACOM is evaluated on the set of DIMACS-W problem instances by using 8 processors. For 77 instances in this problem set we report the same results. For MANN_a81, PACOM performs better than PTC whereas PTC reports better solutions for MANN_a27 and MANN_a45.

Genetic algorithms make use of a top-down approach in their operators while tabu-search like trajectory heuristics use a constructive manner from bottom to the top. They introduce a chromosome that shows the selected vertices with 0 s and 1 s to construct a clique. It is a difficult job for genetic algorithms to provide valid chromosomes after each crossover and mutation. Therefore, they spend much of their time for valid chromosome verifications. When the best reported references are considered for the solution of the MVWCP, there is no genetic algorithm. This shows the drawback of the genetic algorithms for this specific problem. It is clear from the given experimental results in our tables, the operators developed for the MVWCP are reported to obtain best/optimal solutions.

Speed up and scalability are crucial points to be considered for a parallel algorithm. The PTC algorithm runs on several processors simultaneously. Its nature is island parallel, which means that each processor does not wait or send any data to each other (except the master processor). This behavior of the PTC algorithm provides a cohesive structure during the optimization of each processor. Therefore, it is scalable that as many as new processors are added to the environment, the performance of the algorithm improves whether the execution time is increasing linearly. This is a very good virtue for parallel algorithms. As we have explained before, the main focus of the PTC algorithm is to increase the probability of finding the optimal value rather than speeding up the optimization. Restarting a new solution from a different clique is a very effective way of escaping from local optima and for exploring diversified places by using a parallel computation environment.

Local heuristic algorithms consume most of their time for the fitness evaluation of the new solutions while they are exploring the search space. This is one of the most important disadvantages of the heuristic algorithms. On the average, a fitness evaluation is calculated millions of times even during an ordinary optimization period. Speeding up this process and evaluating the neighbors quickly enhances the performance of the heuristic algorithms significantly.

## 5. Conclusions and future work

We proposed a novel robust and cooperative parallel heuristic algorithm for the MVWCP. The proposed PTC algorithm represents one of the first parallel heuristic algorithms to solve the MVWCP. The PTC competes with state-of-the art algorithms on most of the problem instances with its robust solution quality. Among the algorithms that use the same operators (add, swap and drop), the PTC algorithm can be evaluated as the best performing one with significant improvements. Although parallel heuristic algorithms are very effective approaches, new optimization operators like PUSH and novel intelligent approaches are still crucial tools as well as parallel computation for heuristic algorithms. For future work, we plan to study on an automated parameter tuning parallel tabu search algorithm for the MVWCP. It is also interesting to execute several heuristic approaches (hyper-heuristics) simultaneously in a parallel high performance environment. Hyper-heuristics is a novel approach that can optimize a problem instance by using best of different heuristics. We also believe that finding a chance to optimize the MVWCP by using thousands/millions of processors can provide new best results.

Figure 1: The swap operator exchanges the vertices 1 and 2 from clique $C=\{1,5,6\}$ to produce a new maximum vertex weight clique $C^{\prime}=\{2,5,6\}$. add operator that introduces vertex 3 to the existing clique does not produce a better maximum vertex weight clique.

## Master node

## Finish

Figure 2: Flowchart of the PTC algorithm.

Figure 3: The effect of increasing the number of processors on number of best results.

Figure 4: The effect of increasing the number of processors on the average of hits.

Table 1: Detailed results of PTC algorithm on 80 DIMACS-W benchmark instances. node is the number of vertices, $\omega$ is the maximum clique size, W_best is the best value that is found until now, best-found is the best value found by the algorithm, avgsum is the average of the results, hit is the number of obtained best results, $|C|$ is the cardinality of the obtained maximum weighted clique, avg-iter. is the average iteration performed during optimization.
